Abstract. Background/Aim: The tachykinin mouse hemokinin-1, expressed by the mouse Tac4 gene, produces either analgesia or nociception, interacting with the neurokinin 1 receptor. TAC4 precursor processing is not identical to the processing of the TAC1 precursor, for the release of substance P (amidated undecapeptide). The characterization of the mouse hemokinin-1 sequence was required. Materials and Methods: We developed anti-tachykinin-specific antibodies for the immunoaffinity purification of tachykinins. Results: Using MALDI-ToF, we identified mouse hemokinin-1 as an amidated decapeptide expressed in murine brain and periphery. Furthermore, we interestingly observed an additional mass peak corresponding to acetylated mouse hemokinin-1 and this post-translational modification is brain-specific, not detected in the periphery. Conclusion: We suggest that the N-terminal acetylation of the peptide provides greater potency for ligand–receptor interactions during neural cell signaling.

Tachykinins as a vast family of highly conserved peptides share the signature C-terminal motif FXGLM-NH2 (where X in mammals is F, Y, V; in fish, H, I, and in ascidians T) (1-3). The tachykinin mouse hemokinin-1 (mHK-1) discovered as an autocrine factor during pro-B lymphocyte differentiation introduced the group of endokinins (4) which also comprises human HK-1 (5), and its extended forms endokinin A (EKA) and endokinin (EKB) (6) or truncated forms such as the tachykinin human hemokinin (hHK-1) (4-11) (7). Tachykinins act as agonists on the three mammalian tachykinin receptors neurokinin 1, 2, 3 (NK1, NK2, NK3) with different potencies (5, 8). The hydrophobic C-terminal tachykinin motif activates the receptor, and the C-terminal amidation is crucial for activation (9, 10). Binding studies on the NK1 receptor showed mHK-1 as having similar binding affinity on this receptor as substance P (SP) (11-13) and a similar affinity for each of the mouse, rat and human NK1 receptors (5, 7, 14).

The opposite effects of mHK-1 and SP in thermal hyperalgesia, have suggested that the two peptides could bind to different subtypes of the NK1 receptor (15, 16). The activation of NK1 receptor is related to the release of endogenous proopiomelanocortin, as well as the increased expression levels of the μ-opioid receptor in analgesia (17). Moreover, it was reported that the N- and C-terminal fragments of the mHK-1 elicited opposite biological effects (i.e. inhibition or induction of pruritus) when administered in rats, through the activation of the NK1 receptor (18). Recent evidence showed anxiolytic and anti-depressant-like actions for mHK-1 (19). The nociceptive behaviors induced by mHK-1 were inhibited by NMDA receptor antagonists. A significant increase in glutamate levels was observed, which was reduced by co-administration with NMDA receptor antagonists, suggesting that mHK-1-induced nociceptive effects may be mediated by the NMDA receptor (20). The Tachykinin receptor-1 (TACR1) gene was found among the neurotoxicity-associated genes in brain tissue that were significantly modulated after irradiation, suggesting that catenin-β1 and tumor suppressor-related transcription regulation are significantly activated by radiation and/or minocycline, suggesting minocycline as a potential neuroprotectant against radiation-induced damage (21). Moreover, the TACR3 was shown to be highly expressed in oral squamous cell carcinoma suggesting TAC3 was released by the peripheral sensory nerves which may act in tumor cells and that TACR3 signaling may, in turn, contribute to tumor progression (22).

In the present study, the characterization of mHK-1 sequence and post-translational modifications were investigated. The rat TAC4 precursor comprises mHK-1 flanked by dibasic KR cleavage sites, releasing the decapeptide SRTRQFYGLM-NH₂. Previous studies (4, 7, 8) have reported mHK-1 as an undecapeptide suggesting precursor processing occurring between the K/R residues of the dibasic cleavage site, hence, purification and identification of the peptide mass was required. Antibodies were raised against EKA/B (GKASQFFGLM-NH₂) that efficiently recognized mHK-1 (SRTRQFYGLM-NH₂) and SP, then purified and immobilized on Sepharose beads, to produce an affinity medium capable of isolating endogenous mHK-1 and SP. Captured peptides were separated on RP-HPLC and detected using MALDI-ToF. We identified mHK-1 as an amidated decapeptide expressed in both brain and spleen with an additional mass peak corresponding to a brain-specific N-terminal acetylation.

Materials and Methods

Development of anti-tachykinin antibodies and determination of their reactivity to the peptides SRTRQFYGLM-NH₂ or RPKQPOFGLM-NH₂ with antibody-titre curves. All reagents were purchased from Sigma-Aldrich (Gillingham, UK) unless otherwise stated. Tachykinin antisera were raised in sheep as described previously (5). Two animals were inoculated with the antigen EKA/B coupled to BSA (antisera annotated as BO14 and BO16). Plates (Nunc Immobilizer™ Amino, VWR LTD, Leicestershire, UK) were coated with 200 ng of synthetic peptide. Dilutions of the ovine antisera in albumin-phosphate buffer (0.04 M Na₃H₂PO₄, 0.01 M NaH₂PO₄, and 0.5% (w/v) BSA) were produced and dispensed in duplicate into the wells. After incubating at room temperature, the wells were washed with buffer (0.9% (w/v) NaCl, 0.01% (v/v) Triton X-100) three times. A 1/5,000 dilution of donkey anti-sheep IgG-alkaline phosphatase conjugate in albumin-phosphate buffer was added, incubated for two hours at room temperature and removed. The substrate p-nitrophenyl phosphate was used for the detection of immunoreactivity. Plates were read at 450 nm, and the data were represented as absorbance units.

Purification of anti-tachykinin antibodies recognizing SRTRQFYGLM-NH₂ and SP. Cyanogen bromide-activated Sepharose beads (1 g) were swollen into a 3.5 ml gel, washed with 1 mM HCl, and then suspended in coupling buffer (0.1 M NaHCO₃, 0.5 M NaCl, and 0.5% (v/v) Tween 20, pH ~9). Synthetic SRTRQFYGLM-NH₂ (0.5 mg; custom made by Designer Biosciences, Cambridge, UK) and SP (0.5 mg) were dissolved in 1 ml of the coupling buffer and added into the Sepharose gel (incubated overnight at room temperature). The unbound reactive sites on the Sepharose beads were blocked with glycine (0.2 M, pH ~8), and the gel was loaded onto an Econo-column fitted with a flow adaptor and 30 cm of silicon tubing (BioRad, Hertfordshire, UK). Each ovine antiserum (50 ml) containing a protease inhibitor mixture (Roche, West Sussex, UK), 0.18 g EDTA disodium and 2% (w/v) Na₃N was loaded onto the column. Three columns of washing buffer (PBS containing 0.01% (v/v) Tween-20) were applied. Two columns volume of elution buffer (0.1 M citric acid pH ~2.5) were added and incubated for 5 min; the eluted antibodies (6 ml) were immediately neutralized.

Immobilization of anti-tachykinin antibodies on cyanogen bromide-activated Sepharose beads. Cyanogen bromide-activated Sepharose beads (1 g) were activated and washed with 1 mM HCl and then suspended in coupling buffer. The immunopurified anti-tachykinin antibodies were diluted in coupling buffer, added into the Sepharose gel and incubated overnight at room temperature. Unbound reactive sites were blocked; the blocking agent was removed, and the antitachykinin antibody-Sepharose conjugates were stored in 5 ml of storage buffer (1 M NaCl with 0.02% (w/v) Na₃N and 1 mM EDTA disodium) at 4°C.

Isolation of tachykinins by immunoaffinity purification. One rat brain was homogenized using a 10 ml syringe. Two rat spleens were homogenized using a mortar and pestle while keeping tissues frozen in liquid nitrogen. Each homogenized tissue was suspended in 1 ml of extraction buffer (Bennett’s solution consisting of, 1 M HCl containing 5% (v/v) formic acid, 1% (w/v) NaCl and 1% (v/v) TFA) and incubated overnight at 4°C. The mixture was centrifuged at 7500 × g for 15 min and 1 ml of peptide extract was recovered. The peptide extract was diluted in 9 ml of 0.1% (v/v) aqueous TFA. The diluted peptide extract was loaded onto a C18 Sep-Pak cartridge (Waters, Hertfordshire, UK) previously primed with methanol and equilibrated with 0.1% (v/v) TFA). Peptides were eluted with 1 ml of 60% (v/v) acetonitrile with 0.1% (v/v) TFA, neutralized with 1 M TRIS pH ~10 and concentrated under a continuous flow of N₂. The peptide extract was incubated with 60 μl of anti-tachykinin antibody-Sepharose beads suspended in binding buffer (10 mM EDTA disodium, 0.01% (v/v) octyl β-D-glucopyranoside, 0.02% (w/v) Na₃N, and protease inhibitors mixture in PBS). The final volume of the reaction was 500 μl, which was incubated at room temperature overnight. Next, the beads were washed extensively with working buffer and peptides were eluted incubating with 60 μl of 0.5% (w/v) TFA and centifuging at 700 × g for 5 min.

Separation of enriched peptides on RP-HPLC and detection on MALDI-ToF. RP-HPLC was performed using a Waters 600E system controller (Millipore, Watford, UK) and a Waters 486 Tunable UV absorbance detector system, with a reversed phase C18 column (Vydac 218TP54, Beckman Coulter, High Wycombe, UK). An aliquot of the rat brain and spleen immunoadfinity eluents was injected into the system, and peptides were eluted with a linear gradient starting at 10% acetonitrile with 0.04% (v/v) TFA, taken to 40% over 30 min, and kept constant at 100% for 10 min. The flow rate was set at 0.5 ml/min and absorbance at 205 nm. Fractions of 250 μl were manually collected, and organic solvents were removed under a constant N₂ flow. Each 20 μl fraction was further concentrated with a ZipTip μ-C18 (Millipore, Watford, UK) primed with 50% (v/v) methanol with 0.1% (v/v) TFA and equilibrated with 0.1% (v/v) TFA. Peptides were directly spotted, with α-Cyano-4-hydroxycinnamic acid matrix (Agilent Technologies, Berkshire, UK) dissolved in ethanol with 1% (v/v) TFA, on an MALDI-ToF plate (ground steel Bruker). Peaks were detected using an MALDI-ToF Bruker Autoflex III) instrument with FlexControl software.

Results

Anti-tachykinin antibodies were raised by inoculating two sheep with the same antigen i.e. EKA/B (GKASQFFGLM-NH₂). The anti-sera were capable of recognizing the SP and SRTRQFYGLM-NH₂ peptides. Tachykinins possess a
backbone on the FXGLM-NH$_2$ motif and a charged amide group that makes this motif region very immunogenic; however, in the present study, a different response was observed, between the two sheep, with respect to the yielded antibody titres against SP and SRTRQFYGLM-NH$_2$ (Figure 1A and B). As it appears in Figure 1B, the BO16 antiserum showed a substantially higher titre of antibodies recognizing SRTRQFYGLM-NH$_2$ and SP as compared to the BO14 antiserum and therefore the BO16 purified antibodies were immobilized to yield an affinity medium.

![Figure 1](image)

**Figure 1.** Antibody titre curves of two anti-tachykinin antisera BO16 (squares) and BO14 (diamonds). (A) Binding of the two antisera with SP. The antibody titre curves obtained with normal sheep serum (triangles) were used as a negative control. (B) The antibody titre curves of the same antisera against mHK-1.

A RP-HPLC method was developed for the separation of synthetic SRTRQFYGLM-NH$_2$ and SP. Figure 2A shows the chromatogram of the synthetic SRTRQFYGLM-NH$_2$ with retention time 1,402 s and Figure 2B shows the chromatogram of the elution of synthetic SP with retention time 1,706 s. The elution fraction and mass of the two peptides was confirmed with MALDI-ToF. The sequence SRTRQFYGLM-NH$_2$ has a singly-charged mass [M+H]$^+$ 1257.652 a.m.u. The [M+H]$^+$ of the SP undecapeptide is 1347.735 a.m.u.
Figure 2. Reversed-phase separation of mHK-1 and SP. (A) Elution profile of synthetic mHK-1 (SRTRQFYGLM-NH2). Briefly, the peptide was eluted with a gradient of acetonitrile (dashed red line). The synthetic peptide eluted in fractions 11 and 12 (grey). Forty fractions were collected and the presence of the synthetic mHK-1 was confirmed by MALDI-ToF. The endogenous mHK-1 was separated using exactly the same instrument settings. The peptide was detected using MALDI-ToF in fraction 11 only (fraction shown in green). (B) The elution profile of synthetic SP, eluted with the same instrument settings as for mHK-1. The synthetic SP eluted in fractions 21 and 22 (grey). Endogenous SP (captured from rat brain and spleen) eluted in fraction 21 (blue).

**mHK-1 is a decapeptide with a neuropeptide-specific N-terminal acetylation.** Endogenous tachykinin peptides identified by MALDI-ToF in rat brain and spleen and their modifications are shown in Table I. In Figure 3 endogenous mHK-1 in the rat spleen and brain is shown. The peak seen at m/z 1257.701 corresponds to the mHK-1 decapeptide, and the peak seen at m/z 1273.697 is the mHK-1-methionine sulphoxide (SRTRQFYGLM(S→O)-NH₂). In rat brain, the additional peak seen at m/z 1299.710 (ΔM+42.049 a.m.u) is an acetylated form of mHK-1 (Ac-SRTRQFYGLM-NH₂).
The hydroxyl group of the serine is most probably acetylated by specific serine acetyl-transferases.

The expression of SP in rat brain and spleen. Figure 4 shows SP detected in both rat brain and spleen. The m/z 1347.894 peak corresponds to [M+H]+ SP while the peak seen at m/z 1363.886 is SP-methionine sulphoxide [SP (S→O)]+. Our findings show SP is abundantly expressed in the rat brain (acting as a neuropeptide) and also SP is expressed in high levels in the rat spleen (acting as an autocrine or paracrine factor).

Discussion

The sequence of the mHK-1 was deduced from the nucleotide sequence of the novel cDNA, initially named as PPTC and then as Tac4 gene, using the updated standardized nomenclature (23) and was predicted as an amidated undecapeptide RSRTRQFYGLM-NH₂ (4). Therefore, a more definite characterization of the mHK-1 was required i.e. identification of its M.W. and its sequence, as well as any post-translational modifications apart from the well-established C-terminal amidation. The expression of the mHK-1 in brain has not been clear; Zhang and colleagues reported the Tac4 gene not to be expressed in mouse brain but rather in lymphopoietic cells of the periphery, using a rather insensitive Northern blot analysis; later reports, showed the expression of the Tac4 gene in the rat brain (7, 14, 24).

Our present study has proven mHK-1 as an amidated decapetide with an a.a. sequence and M.W. corresponding to SRTRQFYGLM-NH₂ (Figure 3). This finding is not in agreement with the predicted sequence of mHK-1 as RSRTRQFYGLM-NH₂ (mass 1412.75 Da). We have shown the mass of the mHK-1 as [M+H]+ 1257.701 Da same as the theoretical (1257.652 Da). The mHK-1 peptide (SRTRQFYGLM-NH₂) comprises two monobasic cleavage sites at the R residues, releasing the truncated peptides.
where acetylation occurs (33). Upon release the acetylated acetylation is greater stability for the peptide and potency of neuropeptides and the consensus for the biological role of (32). The TAC4 precursor comprises a signal peptide hence acetyltransferases and de-acetyltransferases. Acetylation is one of the signature post-translational modifications of mHK-1 activates the NK1 receptor located on the C-terminal hexapeptide (25).

In the present study, SP was also purified from rat brain and rat spleen (Figure 4). This finding is well in line with previous reports showing expression of the Tac1 gene in human and rat brain and human spleen (6, 14). Moreover, peptide expression studies have detected SP in the brain using mass spectrometry (26, 27). Spectra obtained from our study showed that SP was detected with high abundance in both tissues; however post-translational modifications were not identified on SP. A whole rat brain was used comprising different types of cells. Neuronal cells would produce the acetylated form of mHK-1, while immune cells the non-acylated form. Further pharmacological investigations would elucidate the potency of the mHK-1 decapeptide for the NK1 receptor.

The structure-activity relationship between mHK-1 as a decapeptide and SP as an undecapeptide may be determined by their binding to their respective receptor. In nociception, the cell signaling is through G-proteins, therefore we can suppose that SP acts on the stimulatory subunits of G-proteins and thus increasing the GTPase activity and eventually the Ca2+, while mHK-1 may act on the inhibitory subunits of G-proteins, therefore, a balance system between nociceptors and analgesia may be in place (bystable systems).

Furthermore, in this study we identified mHK-1 in the rat brain comprising a post-translational modification i.e. acetylation of the hydroxyl group of the serine residue. Acetylation occurs by the enzymes N-acetyltransferases most probably in the Golgi apparatus (28, 29). The peak of the mHK-1 [M+H]+ (1257.661 a.m.u.) and the acetylated form of mHK-1 (1299.710 a.m.u.) could exist in vivo in a ratio suggesting the existence of an acetylation and de-acetylation system controlled by specific enzymes i.e. serine N-acetyltransferases and de-acetyltransferases. Acetylation is one of the signature post-translational modifications of neuropeptides and the consensus for the biological role of acetylation is greater stability for the peptide and potency of the peptide with its receptor (30, 31). Acetylation may protect the peptide from degrading enzymes e.g. neprilysin and also acetylation enhances peptide-receptor interactions (32). The TAC4 precursor comprises a signal peptide hence it is directed into Golgi apparatus and stored in vesicles where acetylation occurs (33). Upon release the acetylated mHK-1 activates the NK1 receptor located on the metasynaptic membrane. De-acetylases present on the metasynaptic membrane de-acetylate the peptide, hence, acting as a potential on/off switch of the NK1 receptor (molecular switch).
